Abstract

Microbial organisms express pathogen-associated molecular patterns (PAMPs) that can stimulate expression of pro-inflammatory mediators following ligation of pathogen recognition receptors. However, both commensal organisms and pathogens can express PAMPs. The immune system can distinguish between commensals and pathogens in part through secretion of the key inflammatory cytokines IL-1\(\beta\) and IL-18. A PAMP such as lipopolysaccharide can induce production of intracellular pro-IL-1\(\beta\) and pro-IL-18, but not their secretion. A second “danger signal”, derived from host-cell molecules that are released from stressed or infected cells, or detected as a PAMP that is present in the cytosol, can stimulate assembly of an inflammasome that activates the protease caspase-1. Caspase-1, in turn, is responsible for processing and secretion of the mature IL-1\(\beta\) and IL-18. Many diverse ligands leading to inflammasome activation have been identified, but the cell signaling pathways initiated by the ligands tend to converge on a small set of common mechanisms.

Introduction

Keeping the body free from invading pathogens is an intricate task that requires cooperation between the innate and adaptive immune systems. The early response to infection is the responsibility of the innate immune system, which exhibits a broad specificity to a wide array of germline-encoded pathogen-associated molecular patterns (PAMPs) through different pattern recognition receptors (PRRs). The PRRs include Toll-like receptors (TLRs), nucleotide-binding and oligomerization domain (NOD)-like receptors (NLRs), retinoid acid-inducible gene I (RIG-I)-like receptors (RLRs), and the C-type lectin receptors (CLRs) (1). The two most-extensively studied PRRs are TLRs and NLRs, which exhibit significant interplay (1). Some NLRs can detect PAMPs and stimulate expression of pro-inflammatory genes (2–4), while other NLRs require the participation of other PRRs in order to promote processing and secretion of the key proinflammatory cytokines, IL-1\(\beta\) and IL-18 (5).

NLRs, a family of cytosolic receptors (also known as CATERPILLERs, NOD-LRRs or NACHT-LRRs), are comprised of three domains which include an effector N-terminus domain,
a central NOD or NACHT domain, and a C-terminus LRR motif. A total of 23 NLR members have been identified in humans and are classified based on their N-terminal domain. CARD-containing NLRCs (NLRC 1-5) and PYD-containing NLRPs (NLRP 1-14) play an important role in inflammation, while the role of BIR-containing NAIPs is not well defined yet. NLRs also exist in other organisms: mice possess 34 members, and plants contain a similar subset of genes termed plant disease-resistance (R) genes (6).

Several members of the NLR gene family are involved in the assembly of a macromolecular protein complex termed the “inflammasome” that leads to the activation of the cysteine protease, caspase-1 (also known as interleukin-1 converting enzyme or ICE), which in turn cleaves pro-IL-1β or pro-IL-18, resulting in secretion of the mature cytokines (7–9). NLRP3, NLRP1 and NLRC4 are among the NLR members demonstrated to activate the inflammasome in cells, while other NLR members have been shown to activate the inflammasome in a cell-free system (Fig. 1). In this review, we will discuss the different types of inflammasomes and focus on recent findings regarding their activation by pathogens and other triggers.

The NLRP3 Inflammasome

The NLRP3 inflammasome (also known as Nalp3, cryopyrin, PYPAF1, CIAS1, and CLR1.1), is the most extensively studied inflammasome to date and is responsible for caspase-1 activation by a vast number of pathogens and other stimuli. NLRP3 inflammasome activation usually requires two signals: the first signal, from PAMPs such as lipopolysaccharide (LPS), stimulates a TLR expressed on the cell surface or in an endosome and promotes the production and intracellular accumulation of immature cytokines (10,11). The second signal, usually derived from danger signals (DSs), also known as damage-associated molecular patterns (DAMPs), such as host-derived ATP or uric acid crystals, ligates the danger signal receptor (DSR) and results in processing and secretion of mature cytokines. Initially, DAMPs were thought to be restricted to molecules of microbial origin, but recent work has expanded the concept to include host-cell material released from dying, infected or other stressed cells, including ATP, adenosine, uric acid, and the chromosomal protein, high mobility group box 1 (HMGB1) (12–17). Stimulation with any of these second signals leads to formation of a large complex containing NLRP3, caspase-1, and the adaptor protein, ASC.

A rapidly increasing number of studies have demonstrated the activation of the NLRP3 inflammasome in response to microbial infections. Bacteria including *S. aureus* and *L. monocytogenes* can activate the NLRP3 inflammasome by triggering K⁺ efflux due to their toxins listeriolysin O, and α-toxin, β-toxin or γ-toxin (18). *M. tuberculosis* and *M. marinum* use their ESX-1 secretion system to regulate secretion of IL-1β and IL-18 in a process that requires the NLRP3 inflammasome (19). Interestingly a recent study showed that *K. pneumonia* requires the NLRP3 inflammasome not only for caspase-1 dependent IL-1β secretion, but also for inducing macrophage necrosis and release of HMGB1, independently of caspase-1 (20). Extracellular HMGB1 binds to its specific receptor, RAGE, inducing secretion of TNFα from macrophages (21), which would thus allow the NLRP3 inflammasome to affect secretion of inflammatory cytokines other than IL-1β and IL-18. Similarly, *N. gonorrhoeae* infection of monocytes causes IL-1β production, pyronecrosis, and HMGB1 release in an NLRP3 dependent manner that requires the activity of the cysteine protease cathepsin B (22). *C. trachomatis*, utilizing its type III secretion system, can stimulate NLRP3 inflammasome dependent caspase-1 activation by causing K⁺ efflux-dependent and ROS production in epithelial cells – moreover, caspase-1 was deemed crucial for chlamydial growth and survival (23). As chlamydial infection also results in release of HMGB1 from infected epithelial cells (24), it is tempting to speculate that the NLRP3 inflammasome may amplify the inflammatory response during chlamydial infection through HMGB1. In contrast, *P. gingivalis* infection on its own can not activate an inflammasome: instead it induces synthesis.
of pro-IL-1β, which can be secreted following NLRP3-dependent activation in infected cells that are treated with the danger signal ATP (25). Conversely, *Mycobacterium tuberculosis* subverts the innate immune response by inhibiting NLRP3 inflammasome activation (26).

The NLRP3 inflammasome can also be activated by viruses such as the Sendai virus and influenza A virus, whose infections can cause caspase-1 dependent IL-1β secretion (27,28). Conversely, NLRP3 inflammasome activation by the influenza virus is also required for lung tissue repair (29). Recently, Modified Vaccinia Virus Ankara (MVA), an attenuated poxvirus used as a vector for AIDS vaccines, was shown to activate the NLRP3 inflammasome, leading to secretion of IL-1β (30).

Furthermore, the fungus *C. albicans*, signaling through the tyrosine kinase Syk, causes NLRP3 inflammasome mediated caspase-1 activation and IL-1β secretion in a process triggered by K+ efflux and ROS production (31,32). The transition of *Candida* from the yeast to the filamentous form (hyphae formation) is important for activation of the NLRP3 inflammasome (33). Heat killed *S. cerevisiae* can also activate NLRP3 inflammasome (34).

Both abiotic and biological crystals can also activate the NLRP3 inflammasome. Thus, asbestos, silica and amyloid-β fibrils induce NLRP3-dependent caspase-1 activation following “frustrated phagocytosis” of the large crystals or lysosomal leakage (35–38). In this context, NLRP3 could play both beneficial and deleterious roles, by inducing inflammation in response to environmental particles or during Alzheimer’s disease. The ability of host cells to respond to DAMPs through inflammasomes also explains the ability of alum, chitosan and QuilA/saponin to behave as potent adjuvants (39,40).

More recently, hemozoin, a heme crystal produced by malaria causing parasite *Plasmodium*, was shown to similarly activate NLRP3 inflammasome by acting as a danger signal through the Lyn/Syk kinase pathway (41,42).

The NLRP3 inflammasome initially gave the impression of being rather promiscuous, as it could be activated by a wide variety of stimuli, ranging from toxins, ATP and uric acid crystals. However, these disparate stimuli stimulate NLRP3 through a small number of shared mechanisms (Fig. 2). Thus, the K+ efflux is induced by microbial toxins (18,43), imidazoquinoline derivatives (44), and infection by *C. albicans* or *C. trachomatis* (23,31–33), and extracellular ATP (45,46). ATP can stimulate K+ efflux due to the association of the purinergic receptor, P2X7, with the recently-discovered hemichannel, pannexin-1 (47,48), which allows formation of large non-selective pores in the membrane. Pannexin-1 in fact has been shown to be necessary for ATP-induced IL-1β secretion (47,49).

ATP stimulation of macrophages can also induce formation of reactive oxygen species, which lead to caspase-1 activation (50). The antioxidant N-acetylcysteine can inhibit both ATP-mediated caspase-1 activation and, interestingly, NLRP3 inflammation activation due to treatment with ionophores such as nigericin (43,50).

Finally, destabilization of lysosomes by silica crystals, amyloid-β fibrils and alum salts has been shown to activate the NLRP3 inflammasome (36,37). Rupture of lysosomes causes release of the lysosomal protease, cathepsin B, which is somehow sensed by the NLRP3 inflammasome.

**The NLRP1 Inflammasome**

NLRP1 (also known as Nalp1, CARD7, NAC, DEFCAP, and CLR17.1) forms an inflammasome containing caspase-1 and ASC. It is stimulated by the presence of cytosolic muramyl-dipeptide (MDP), which results in activation of caspase-1 (51). Studies with a
reconstituted NLRP1 inflammasome in a cell-free system demonstrated that caspase-1 activation occurs in a two-step mechanism whereby MDP triggers a conformational change in NLRP1, allowing it to oligomerize into the inflammasome after binding nucleotides (52).

Separate studies on the NLRP1 inflammasome were carried out in mice, which possess three NLRP1 paralogues (NLRP1a, NLRP1b and NLRP1c), compared to the sole NLRP1 gene in humans. Susceptibility of macrophages to lethal toxin (LT), a metalloproteinase responsible for B. anthracis pathogenesis, is mediated by an NLRP1b inflammasome through an unknown mechanism (53). Transfection of fibroblasts with NLRP1b and caspase-1 conferred susceptibility of these cells to anthrax LT (54).

The NLRC4 Inflammasome

The NLRC4 inflammasome (also known as IPAF, CARD12, CLAN, and CLR2.1) is activated by some Gram-negative bacteria possessing type III or type IV secretion systems. These bacteria include S. typhimurium, S. flexneri, P. aeruginosa and L. pneumophila (55–60). An initial study showed that caspase-1 activation and subsequent IL-1β and IL-18 maturation in response to S. typhimurium infection requires the assembly of the NLRC4 inflammasome (56), and later work demonstrated that NLRC4 senses the presence of flagellin in the cytosol aided by the type III secretion apparatus (61,62). Similarly, L. pneumophila utilizes its Dot-Icm type IV secretion system to activate the NLRC4 inflammasome and caspase-1, which then restricts growth of Legionella in macrophages (60). Flagellin from Legionella was shown to be the trigger for assembly of the NLRC4 inflammasome (63). A recent study showed that L. pneumophila can also induce caspase-1 activation independently of NLRC4, through a pathway involving ASC and triggered by loss of intracellular K⁺ (64).

Unlike Salmonella and Legionella, S. flexneri does not possess flagellin, yet is still capable of activating the NLRC4 inflammasome through a process that requires an intact type III secretion system (59). Although initial studies showed that NLRC4 inflammasome activation following P. aeruginosa infection requires flagellin and an intact type III secretion system (55,57), it was also found that either the non-flagellated strain PA103/g507U or the flagellin-deficient mutant strain PAK/g507fliC can also activate the NLRC4 inflammasome, leading to IL-1β secretion (58). These results suggest the existence of a flagellin-independent mechanism for NLRC4 inflammasome assembly.

Inflammasome Activation by AIM2

Four recent studies have reported that cytoplasmic dsDNA is sensed by a PYHIN (pyrin and HIN domain-containing protein) family member: AIM2 (absent in melanoma 2) (65–68). Although it is not an NLR family member, AIM2, upon binding cytoplasmic dsDNA through its carboxy terminal domain, oligomerizes and interacts with ASC through its amino terminal pyrin domain. This interaction causes the formation of an ASC pyroptosome or AIM2 inflammasome which ultimately leads to activation of caspase-1 (66,67) and NF-κB (67).

Concluding Remarks

All the cases studied until now point to the importance of inflammasomes in the innate immune response against infection or nonliving particles. There is a clear interplay between TLRs and NLRs for optimal production of IL-1β and IL-18. Even though the flurry of recent reports have clarified our comprehension of the mechanisms underlying inflammasome activation, many unanswered questions remain.

The inflammasome complexes differ from each other with respect to their activating stimuli. NLRC4 is activated during infection with mostly flagellated bacteria (55–60), but the
mechanisms through which non-flagellated bacteria activate NLRC4 remain unknown (58). NLRC4 is hypothesized to directly or indirectly sense membrane damage caused by these pathogens via their type III secretion system and not through any pathogen-derived molecules. This might also be the case for *F. tularensis*, which requires ASC but not NLRC4 in order to induce caspase-1-mediated cell death in macrophages (69).

NLRP1 in humans senses the presence of MDP, a subcomponent of peptidoglycan (51,52), but its putative paralogue in mice, NLRP1b, exhibits a different ligand-specificity as it is activated by LT during *B. anthracis* infection (53). Functional homologs of these NLR members may be present in humans and mice, as the equivalent inflammasomes in the two species have not been identified through sequence homology.

Until far, NLRP3 has been associated with the widest variety of stimuli, which makes it unlikely that all these activators trigger inflammasome assembly by direct interaction with NLRP3. Instead they appear to stimulate common signaling pathways that converge on NLRP3 activation. Some of the events leading to NLRP3 activation are K⁺ efflux (18,43), ROS production (43,50), and cathepsin B release from lysosomes (36,37).

The link between K⁺ efflux and ROS production in NLRP3 activation also deserves more attention. Results from at least two studies suggest that K⁺ efflux precede ROS production: the use of anti-oxidants prevents ionophore-induced NLRP3 activation (43), and blocking K⁺ efflux inhibits ROS production (23). Plasma membrane depolarization has been previously shown to activate NADPH oxidase (70,71), suggesting a mechanism for ROS production in cells subjected to danger signals that stimulate NLRP3 assembly.

The inflammasome field is expanding quickly, attracting some of the most talented researchers in immunology and cell biology. Future studies will undoubtedly elucidate the functions of remaining NLRs as well as the ultimate triggers responsible for their activation.

Figure 1.
Both a pathogen recognition receptor (PRR) and Nod-like receptor (NLR) family member are usually required for secretion of IL-1β. Binding of a pathogen-associated molecular patterns (PAMP) to its PRR results in pro-IL-1β synthesis, but not always secretion of IL-1β. A second signal, derived from an extracellular “danger signal” such as ATP or gout crystals, or an intracellular PAMP such as muramyl-dipeptide (MDP) from peptidoglycan activate an inflammasome consisting of caspase-1, the adaptor protein ASC, and a NLR family member or AIM2. LT, lethal toxin from \textit{Bacillus anthracis}; dsDNA, double-stranded DNA. Inflammasome-dependent caspase-1 activation results in processing and secretion of the mature IL-1β.
Figure 2.
Diverse danger signals lead to NLRP3 inflammasome activation through common mechanisms. Extracellular damage-associated molecular patterns (DAMPs) can lead to K⁺ efflux and then ROS production, or directly to ROS production. Large particles can also cause lysosomal destabilization and release of enzymes such as cathepsin B. Either high ROS levels or cytosolic cathepsin B can stimulate the NLRP3 inflammasome, leading to caspase-1 activation.
